Nonresponse and Sample Weighting in Organizational Surveying

Abstract

Post-stratification weighting is a common procedure used in public opinion polling applications to correct demographic constituency differences between samples and populations. Although common practice in public opinion polling, this form of data remediation is only lightly acknowledged as a procedural topic worthy of empirical investigation within the organizational surveying literature. The current paper induces survey nonresponse via data simulation across fictional constituent groups (aka organizational strata) and documents the impact of weighting on the accuracy of sample statistics. Our goal was to evaluate the effectiveness of weighting when confronted with *passive* versus *active* forms of nonresponse in an effort to: 1) interject this data-remediation procedure into the established organizational surveying literature focused on nonresponse, while also 2) exploring organizationally-relevant sampling scenarios that: a) benefit from, b) are "hurt" by, or c) are unaffected by post-stratification weighting. The results confirm that sampling contexts characterized by active nonresponse do benefit from application of sample weights, but only when accompanied by constituency differences in underlying population construct (e.g., surveyed *attitude*) standing. Alternatively, constituent member differences in population attitudes, when characterized by passive forms of nonresponse, exhibit no benefit from weighting (and in fact these scenarios are somewhat *hurt* by weighting). The simulations reinforce that, moving forward, it would be prudent for surveyors of all disciplinary backgrounds to mutually attend to the traditional focus of both traditions: public opinion polling (e.g., multiple possible methodological sources of error as well as post-stratification adjustment) and organizational surveying (e.g., *form* of nonresponse).

Keywords: Survey methodology, sample weighting, nonresponse, response rate

Nonresponse and Sample Weighting in Organizational Surveying

Akin to differential variable weighting (for instance: a) construct indicators within a multi-item assessment scale [aka factor loadings], or b) predictors within a selection system [aka regression weights]; e.g., per data matrix "columns"), sample weighting alters the proportional contributions of *individual respondents* within a data set (e.g., data matrix rows). Some respondents' responses are assigned greater relative contribution and others are assigned less. This practice is commonplace in the summary of general population polling data reflecting, for example, elections and politics (e.g., Rivers & Bailey, 2009), prevalence rates of psychological disorders (e.g., Kessler et al., 2009), or feelings of physical safety (e.g., Quine & Morrell, 2008). It is also seemingly in the periphery of awareness and interest within the published organizational surveying literature (see, for example, Kulas et al., 2016; Landers & Behrend, 2015; Tett et al., 2014).

We speculate that this form of statistical remediation is gaining research interest in the organizational surveying research domain, at least in part, because industrial psychologists are keenly aware that response rates within organizational surveying applications have been trending downward (see, for example, Anseel et al., 2010; Rogelberg & Stanton, 2007). With lower response rates, surveyors are confronted with heightened levels of scrutiny because, historically, a locally realized high response rate has been widely interpreted as a positive indicator of data quality (e.g., Anseel et al., 2010; Cycyota & Harrison, 2002, 2006; Frohlich, 2002). The orientation of this presentation, however, is that although response rate is a commonly referenced proxy of survey quality, it is not response rate but rather sample representativeness that should be the primary focus of concern for survey specialists (see, for example, Cook et al., 2000; Krosnick, 1999). Representativeness can of course be "hurt" by low response rates, but the relationship between these two survey concepts is by no means exact (e.g., Curtin et al., 2000; Keeter et al., 2006; Kulas et al., 2017). Stated differently, a high response rate is neither a sufficient nor necessary condition for representative population sampling.[1]

In the context of any survey application, population misrepresentation ultimately refers to a discrepancy between estimated sample statistics and actual population parameters. Ideally, such discrepancies arise from completely random sources (in which case resulting error is less likely to be reasonably characterized as bias). In reality, however, discrepancies are driven not only by purely random causes. There are several broader sampling methodology factors that may be systematically driving the relative under- or over-selection of a population segment (see, for example, Kulas et al., 2016), but the most commonly cited contributor within the organizational sciences is non-response (e.g., invited individuals simply either forget or consciously choose not to participate in the survey process, see, for example, Rogelberg et al., 2000). Our presentation also focuses on this non-response contributor to sample misrepresentation, but only because we aim to: 1) integrate the organizational non-response and public-opinion post-stratification weighting literatures, while also 2) highlighting the associations and dissociations between response rate and misrepresentation (although we also note here that the current presentation and procedure address additional sampling methodological sources of misrepresentation).[2]

[1] Statistical benefits exist that are commonly attributed to higher response rates, such as greater power. These benefits, however, do not originate from response rate, but rather its consequence: larger *n*. Our presentation reflects the fact that greater power (and/or, relatedly, smaller confidence intervals) may in fact foster a false sense of confidence regarding "data quality". Primarily for this reason, we stress that the methodological/statistical concepts of response rate, sample size, and power should be fully disentangled from the principle of representativeness, and the importance of these dissociations drives the central theme of the current paper.

[2] Frequently presented as a separate consideration, *measurement error* is an additional contributor to population misrepresentation. The current focus is on deviations from a perfect sampling methodology as opposed to deviations from an ideal psychometric methodology. We do however note that future advancements within the broad domain of "survey error" would benefit from a unified perspective that encompasses error arising from both methodological sources: measurement and sampling strategy.

Nonresponse in Organizational Surveying

Within the organizational surveying domain, it is not uncommon for response rate (RR) to be referenced as a proxy for survey data quality (see, for example, Baruch & Holtom, 2008; Fan & Yan, 2010; Pedersen & Nielsen, 2016). Baruch (1999), for example, states that, "...to have dependable, valid, and reliable results, we need a high RR from a wide representation of the whole population under study" and that, "The level of RR is an important, sometimes crucial, issue in relation to the validity of a paper's results" (p. 422). Fan and Yan (2010) similarly state that response rate is, "...the most widely used and commonly computed statistic to indicate the quality of surveys" (p. 132). Pedersen and Nielsen (2016) claim that a high survey response rate, "...diminishes sampling bias concerns and promotes the validity of survey-based research findings" (p. 230). The general consensus seems to be that there are three major (negative) consequences of low response rates, including (a) yielding smaller sample size, which negatively impacts statistical power and confidence intervals, (b) reducing the credibility of survey data, and (c) generating biased samples that impair the generalizability of survey results (Biemer & Lyberg, 2003; Luong & Rogelberg, 1998; Rogelberg et al., 2000).

To the likely frustration of those who associate response rate with survey data quality, organizational survey response rates have, on average, been declining for decades. Baruch (1999), for example, summarized response rates of 175 studies published in five leading management and behavioral sciences journals in 1975, 1985, and 1995. His results revealed an average response rate (across time periods) of 55.6% (SD = 19.7%), but also a trend within which response rates declined steadily from 64.4% to 55.7% to 48.4% over the three time points. Nine years later, Baruch and Holtom (2008) conducted a follow-up study of 1,607 studies published in 17 disciplinary-relevant journals in 2000 and 2005 but found no substantial differences in response rates compared to those in 1995, suggesting that the declining trend had perhaps reached a lower asymptote. However, a different approach with similar goals (Anseel et al., 2010) analyzed 2,037 survey projects published in 12 journals in Industrial and Organizational Psychology, Management, and Marketing from 1995 to 2008 and did note a slight decline (overall $M = 52.3\%$) when controlling for the use of response enhancing techniques.[3] The most recent like-minded review focused on the years 2010, 2015, and 2020 and noted a possible reversal of the trend, such that average response rates had risen to 68% in 2020 (Holtom et al., 2022).

Form of Nonresponse

Although high response rates are generally pursued as desirable within organizational surveying applications, there has also been a broad acknowledgement that not all forms of nonresponse should be considered equally worrisome. Rogelberg et al. (2003), for example, propose a distinction between active and passive nonrespondents based on intent and (in)action. According to Rogelberg et al. (2003), active nonrespondents are those who intentionally refuse to participate in surveys, while passive nonrespondents are those who fail to respond to surveys due to reasons such as forgetting or misplacing invitations. Passive nonrespondents are thought to be similar to respondents in both attitude (Rogelberg et al., 2003) as well as organizational citizenship behaviors (OCBs, Spitzmüller et al., 2007), whereas active nonrespondents have been shown to exhibit significantly lower organizational commitment and satisfaction, higher intention to quit, lower conscientiousness, and lower OCBs than actual respondents (Rogelberg et al., 2000, 2003; Spitzmüller et al., 2007). Additionally, it has been noted that selection of an individual population element into a realized sample may in fact be predictable (because of, for example, an increased likelihood of not responding when dissatisfied or disgruntled, Taris & Schreurs, 2007).

[3] It is also possible that the declination had stabilized with mean response rates hovering around 50% after roughly the turn of the millenium ($M = 52.5\%$ for HRM studies from 2009 to 2013, Mellahi & Harris, 2016; $M = 52.0\%$ for management studies from 2000 to 2004, Werner et al., 2007). This stability, if authentic, may again possibly be accounted for by an increased contemporary emphasis on response enhancing strategies (Anseel et al., 2010; Fulton, 2016).

The more commonly encountered form of organizational nonresponse appears to be passive (Rogelberg et al., 2003; Rogelberg & Stanton, 2007), although subgroup rates may evidence variability - men, for example, have a higher proclivity toward active nonresponse than do women (Luong & Rogelberg, 1998; Rogelberg et al., 2000; Spitzmüller et al., 2007). The organizational surveying baseline default expectation is that, *on average*, roughly 15% of nonrespondents should be expected to be accurately characterized as "active" (Rogelberg et al., 2003; Rogelberg & Stanton, 2007; Werner et al., 2007). It is this second, less frequently anticipated form of nonresponse that also carries the greater resulting threat of biased sample estimates (see, for example, Kulas et al., 2017; Rogelberg & Stanton, 2007). It is these biased estimates that are the desired target of remediation when applying sample weights.

Sample Weighting - a Brief Overview

Within public opinion polling contexts, when realized sample constituencies (e.g., 44% male - by tradition from *carefully-constructed* and *randomly sampled* data frames)[4] are compared against census estimates of population parameters (e.g., 49% male), weights are applied to the sample in an effort to remediate the relative proportional under- or over-sampling. This is because, if the broader populations from which the under- or over-represented groups are sampled differ along surveyed dimensions (e.g., males, within the population, are *less likely to vote for Candidate X* than are women), then unweighted aggregate statistics (of, for example, projected voting results) will misrepresent the true population parameter. This remedial application of sample weights should also be considered an option for researchers pursuing answers to analagous organizational pollings

[4] These important sampling concepts are very carefully attended to within public opinion polling contexts. Conversely, within organizational surveying traditions, these considerations are not commonly acknowledged, at least explicitly within the published literature. The weighting procedure presented in the current manuscript remediates bias regardless of the methodological source, but is dependent on accurate "census" population constituency estimates.

such as: "What is the mood of the employees?" This is because focused queries such as this are of course covertly complex - implicit in the question is a focus not on survey results, but rather the broader employee population. Acknowledging the appropriate object of attribution is of course important, because the next step (after gauging the mood of the surveyed respondents) is *doing something* about it. Weighting may be a procedural option for organizational surveyors to credibly transition a bit closer from, "What do the survey results say"? to "What do the employees feel"?

Procedural application

Proportional weights are the form of weights most directly relevant to organizational surveying applications that traditionally focus on nonresponse as the primary contributor to sample misrepresentation. These weights are ratios of the proportion of a population within a given stratum to the proportion of the sample within that same stratum:

$$proportional\ weight(\pi_k) = \frac{(N_k/N)}{(n_k/n)} \tag{1}$$

Over-sampling of elements of a stratum (k) results in proportional weights less than one, while under-sampling (relative to the population) results in proportional weights greater than one. The common procedure for weight estimation *when more than one stratum is specified* is an iterative process that may be referred to by multiple substantively synonymous terms: *rim weighting*, *iterative proportional fitting*, or *raking* (see, for example, Deming & Stephan, 1940). Regardless of label, the procedure guides the surveyor to:

1) Determine proportional weights for all levels within one stratum, and then assign these weights to cases.

2) Determine proportional weights for a second group (ratio of population percent to *current* sample percent [the current sample percent will be affected by the step 1

weighting procedure]). Multiply previous (step 1) weights by the proportional weights for this second stratum and assign these new weights to cases.

3) Determine proportional weights for a third stratum (which will once again require re-inspection of the *current* sample percent). Multiply the previous step 2 weights by the third stratum proportional weights and assign to cases.

4) Iterate through steps 1, 2, and 3 (or more if more than three strata are considered) until the weighted sample characteristics match the population characteristics to your desired level of precision.

Possible strata relevant for organizational survey weighting include: branch, full-, part-, or flex-time status, functional area, gender, geographic location, hierarchy, remote-working categorization, salaried status, subsidiary, tenure, work shift, or any other groupings especially suspected to plausibly possess a relatively disporportionate number of active nonrespondents (through application of forecasting strategies such as those advocated by, for example, Rogelberg and Stanton, 2007). Each of these strata may of course also be the targeted focus of survey results feedback, but when *aggregating* results across (or even within) strata, a consideration of the impact of nonresponse *has the potential* to yield more accurate survey estimates. The explicit goal is therefore a closer approximation of descriptive sample statistics to population parameters via statistical remediation, and drives the current paper's focus on the interplay of four survey elements: 1) distribution of attitude within the larger population, 2) response rate, 3) nonresponse form, and 4) remedial weighting.

Research question 1: What role does overall response rate play in population misrepresentation?

Research question 2: What role does nonresponse form (passive versus active) play in population misrepresentation?

Research question 3: What impact does the application of weights have on both biased[5] (e.g., misrepresentative) and unbiased sample estimates?

We view these questions as being analogous to similar questions asked and answered with differential variable weighting within the broader applied psychological disciplines. Just as, for example, there has been debate regarding the merits of differential versus unit variable weighting in a selection context or aggregate scale score definition (e.g., Bobko et al., 2007; Wainer, 1976), we propose that a similar consideration is appropriate with persons, and therefore compare and contrast unit- versus variable-sample element weighting.

Methods

We address our research questions within a simulated fictionalized context of organizational surveying (wherein it is common to assess estimates of employee attitude or perception; for example, commitment, culture/climate, engagement, satisfaction). We began the simulations by establishing "populations", each consisting of 10,000 respondents characterized by demographic categorizations across gender (male and female) and department (A and B). We therefore had four demographic groups (male-A, male-B, female-A, and female-B). For these population respondents, we generated scaled continuous responses (real numbers) ranging from values of 1 to 5, representing averaged aggregate scale scores from a fictional multi-item survey with a common $1 \rightarrow 5$ Likert-type rating scale.

In order to represent different proportions of relative constituency (for example, more females than males or more department A workers than department B), we iterated population characteristics at marginal levels (gender and department) starting at 20% (and 80%) with increments and corresponding decrements of 20%. For example, if males

[5] We have to be careful about the use of the term "bias" - either very carefully distinguish between error and bias or just avoid use of the term altogether. Perhaps Dr. Robinson can help here.

accounted for 20% of the simulated population, then females were 80%; also if respondents in Department A represented 60% of a population, then 40% were in Department B. Marginal constituencies were therefore specified at all combinations (across the two variables) of 20% and 80%, 40% and 60%, 60% and 40%, and 80% and 20%. This resulted in population *cell* constituencies (e.g., men in department A) as low as 400 and as high as 6,400.

Additionally, each of these cell populations was characterized by an attitudinal distribution in one of three different possible forms: normal, positively skewed, or negatively skewed. These distributional forms were specified in an attempt to model similarities and discrepancies in construct standing (e.g., commitment, satisfaction, or engagement) across respondent groupings. The normal distribution exhibited, on average, a mean of 3.0 whereas the skewed distributions were characterized by average means of 2.0 and 4.0, respectively. In total, eight crossings of distributional type across employee categorization were specified (Table 1 presents the combinations of these distributions). Note that these eight conditions are not exhaustive of all possible combinations of constituent groups and attitudinal distribution - we limited the simulations to combinations that we projected to collectively be most efficiently informative.

Individual attitudes were randomly sampled from population distributions at the cell level (e.g., Department A Males) without replacement. Response rates (methodologially these could also be conceptualized as *sampling* rates) were controlled at the marginal level using 10% increments ranging from 60% to 90%, and these were fully iterated. Our cell-level response rates therefore ranged from 36% to 81% - a range of rates chosen because they are reasonable expectations according to the organizational surveying literature (e.g., Mellahi & Harris, 2016; Werner et al., 2007). We therefore investigated error within the aggregate mean (e.g., grand mean or total sample mean) attributable to different likelihoods of sample inclusion from constituent groups of different relative size and representing populations of different attitudinal distribution, but at response rates reasonably expected to exist in real-world organizational surveying contexts.

It should be noted here that there are several collective patterns of response that are intended to represent sampling scenarios reflecting *passive* nonresponse across groups, regardless of response rate. These are the scenarios in which all subgroups exhibit the same response rate (e.g., 36%, 36%, 36%, and 36%). All other combinations of response rate are intended operationalizations of active forms of nonresponse (e.g., not *as reasonably* characterized as missing at random), although the degree to which a sampling scenario should be reasonably considered to be reflecting active nonresponse is intended to increase incrementally across response rate conditions.

In an attempt to capture this "degree of active nonresponse", we calculated a simple index of response rate discrepancy (SD; presented in Table 2). The "least" active nonresponse scenarios are characterized by two subgroups with identical response rates and two having a slightly different response rate (e.g., Dept A Males = 36%, Dept A Females = 36%, Dept B Males = 42%, and Dept B Females = 42%; see the second row of Table 2, the SD index = .034)[6]. Also here note that three of our eight Table 1 conditions represent scenarios where the presence of active nonrespondents is not expected to result in bias (e.g., regardless of patterns of nonresponse, the unweighted sample mean is expected to yield an unbiased estimate of the population mean). These are Table 1 conditions one through three, where attitudinal distributions are of *the same form* across groups, regardless of any individual group response rate discrepancy from others'.

[6] This method of simplifying the presentation of our response rate conditions is fully independent of consideration of population constituency and distributional form. That is, the amount of bias present in a sample estimate is expected to be quite different for Condition 7 with response rates of 48%, 48%, 72%, 72% versus 48%, 72%, 48%, 72%, even though the crude response rate index (SD = 0.139) is the same for both scenarios. There is additional information within these simulations (the effect of a *combination* of response rate and population form on degree of bias) that is therefore not captured via this simple SD index.

These operationalizations of passive and active forms of nonresponse differ from other investigations with similar goals. Kulas et al. (2017), for example, directly tie probabilities of sample inclusion to an individual's held attitude (the likelihood of sample inclusion is fully dependent on the population member's attitude). Conversely, the probability of sample inclusion in the current investigation is dependent only on *group* membership (with some of these groups occasionally being characterized by unique attitude distributional forms). Essentially, Kulas et al. (2017) operationalize active nonresponse at the person-level whereas the current paper does so at the group level. This may be a more appropriate procedural specification with regard to the implications of these simulations, as organizational surveyors are more likely to have an inclination of a group's collective attitude or likelihood to respond (e.g., night shift workers, machine operators) than they are of any one individual employee.

Results

In total, we generated 327.68 million samples (4,096 unique combinations of response rate and population constituency across gender and department, simulated 10,000 times each across our eight Table 1 conditions). Each of these samples was comprised of, on average, n = 5,625, collectively representing an experiment-wide simulated n of 1.8432 trillion. For each individual simulation, weights were applied iteratively to the data at the two marginal (variable) levels via raking, and were estimated via the *anesrake* package (Pasek, 2018) in R version 4.1.1 (2021-08-10).

We were most interested in comparing the extent to which unweighted (aggregated responses without raking) and weighted (aggregated weighted responses) sample means approximated the known population means across our controlled specifications of response rate, nonresponse form, and attitudinal distribution. Population means were extracted from each iteration, as the simulations specified a new population at each iteration. The "misrepresentation" betwen sample and population was operationalized by calculating: 1) the discrepancies between the population and both weighted and unweighted sample means, as well as, 2) the averaged deviations of these discrepancies from the population mean (discrepancy in the "mean" of the means is bias, dispersion about the "mean" of the means is error). If the average weighted sample mean was closer to the true population mean, relative to the unweighted one, then the weighting was deemed beneficial.[7]

Yet to do:

1. means and standard deviations (report at least in overall response rate section)
2. find the polynomial regressions and report
3. correct the .51 estimate in the Cattell section
4. find the figure with "red" and "grey" standard error bars (standard error section)

Role of overall response rate

Research question 1 asked what role overall response rate plays in population misrepresentation. This is presented most directly in Figure 1, with *moderate* response rates exhibiting the greatest degrees of misrepresentation across our simulated conditions. Note here again that conditions 1 through 3, which represent populations with similar distributions of attitude, do not exhibit misrepresentation regardless of response rate. These can be contrasted with conditions 6 through 8, which evidence considerable misrepresentation, particularly so at moderate response rates (the greatest degree of misrepresentation occurs with response rates ranging from roughly 40% to 70%).[8]

[7] Do we want to do a little more with the dispersion concept? Currently it's underreported in the Results (but stated here that it is something we look at). If so, do we say that the weighting was beneficial also if the dispersion (error) was relatively small?

[8] **NEEDS FURTHER THOUGHT/EXPLANATION** Middle range more cases - for the lowest case, there's only 256 cases (all with the same response rate of 36%). That explains the "upward slope" on the left of the graphing spaces. Clarification here would state that *these graphs hint to form of nonresponse being important - the lowest and highest response rates are constrained such that all groups have the*

Role of nonresponse form

Research question 2 asked what role the *form* of nonresponse (passive versus active) plays in population misrepresentation. In terms of explaining the error that did emerge within unweighted means sampled from conditions 4 though 8, this error was largely attributable to form of nonresponse as operationalized by our SD index (See Figure 2). Figure 2 also adds information to the Figure 1 response rate relationships, with the most extreme misrepresentation paralleling circumstances of active nonresponse (e.g., to the "right" in the figures). The nature of the exact relationship was slightly nonlinear, being fit with quadratic functions within each condition (collapsing across conditions did exhibit slight within-array differences [which would affect the statistically perfect relationship]).[9]

The systematic patterns of heteroskedasticity of the Figure 2 scatterplots should also be noted. There are *active nonresponse* scenarios in which no error is present (see, for example, the lower right-hand portions of conditions 4 through 8 in Figure 2 where discrepancy estimates of "0" appear all along the passive-active x-axis). These circumstances are simulated conditions within which the response rates "parallel" the distributional form. For example, in Condition Eight, the distributional forms were: $PositiveSkew_{Male(A)}$, $PositiveSkew_{Male(B)}$, $NegativeSkew_{Female(A)}$, $NegativeSkew_{Female(B)}$. In the most extreme cases of active nonresponse, marginal response rates that fully parallel distributional patterns (e.g., $20\%_{\text{Male(A)}}$, $20\%_{\text{Male(B)}}$, $80\%_{\text{Female(A)}}$, $80\%_{\text{Female(B)}}$) result in no error in the population mean approximation (average discrepancy = .0003, *SD* = .0002). Alternatively, when the response rates are inverted, (e.g., $20\%_{\text{Male\_A}}$, $80\%_{\text{Male\_B}}$, $20\%_{\text{Female\_A}}$, $80\%_{\text{Female\_B}}$), there is substantial error

same/similar levels of response rate - this is our operationalization of passive nonresponse.

[9] Need to find these analyses if retain - Figure 2 looks linear with heteroskedasticity (6/16/23). Talking with Yang 6/30/23 we DID run these analyses. Look in older versions of the paper for a description of the analyses.

in approximation (average discrepancy = .51, SD = .14). [10] Again, it is not merely response rate or form that is associated with biased sample estimates, but rather the nature of response rate relative to existing attitudinal differences.

To partially address this moderation, the discrepancies between population constituency and sampling proportions were additionally evaluated through the lens of Cattell's profile similarity index (r_p, Cattell, 1949; Cattell et al., 1966). r_p is sensitive to discrepancies in profile shape (pattern across profile components), elevation (average component score), and scatter (sum of individual components' deviation from the elevation estimate. Figure 3 demonstrates the pattern of unweighted sample mean deviation (from the population parameter) when this index is taken into consideration. Specifically, Figure 3 demonstrates a more pronounced *form of* nonresponse association when underlying attitudinal distributions evidence group differences, and in these scenarios, active nonresponse is shown to have a fairly large effect on error within the sample estimate (as well as systematically increasing degrees of heteroskedasticity paralleling the Cattell index; omnibus Breusch-Pagan = 3177.2, $p < .001$).

Impact of weighting

Research question 3 was focused on the impact of weights on both biased (e.g., misrepresentative) and unbiased sample estimates[11]. Figure 4 provides a broad summary of the results across the eight different attitudinal distribution conditions, presenting the average absolute discrepancy from the population mean for the weighted and unweighted sample estimates. Conditions one through three demonstrate that, on average, the unweighted sample mean provides a good (unbiased) estimate of the population mean when the distributional form does not differ across constituent groups (e.g., the

[10] Need to redo this - .51 doesn't appear on graph, highest should be .2

[11] Come back to this phrasing after decision is made on RQ 3 wording (whether to avoid using the term bias or not).

distributions of attitudes are of similar functional forms and locations for all constituent groups). This is regardless of form or extent of nonresponse. Additionally, weighting remediates deviations about the true mean in all five attitudinally discrepant conditions, even when substantive relative error exists in the unweighted estimate (e.g., the rightmost bars in Figure 4). Although the *patterns* of unweighted sample mean discrepancies differed across conditions, all eight conditions exhibited similar omnibus effect (weighting ameliorating error wherever it arose [in the unweighted statistic]).

To further elaborate this point, consider, for example, Condition 4 as presented in Table 1. Here, three groups are characterized by similar distributions of attitudes (normally distributed) and one, Females from Department B, is characterized by negatively skewed attitudes. The greatest unweighted error here arises from sampling scenarios in which there are many Department B females (e.g., in our specifications, 6,400) and fewer males and Department A females[12], but the Department B females exhibit a much lower response rate (e.g., 20%) than do other groups, who respond at a high rate (e.g., 80%). That is, it is not merely response rate, but response rate within these identifiable groups, and whether or not those response rate differences parallel underlying attitudinal differences that drives sample misrepresentation.

Weighting and Sampling Error

Mean square error is our second index for sample quality. It is a well-known mathematical theorem that the application of weights increases (random) errors of precision, which was also empirically true in the current study. For each condition in our simulations, we calculated the standard deviations of 40.96 million unweighted and 40.96 million weighted samples means (4,096 possible population-sample combinations by 10,000

[12] Because of the “marginal” versus “cell” specifications of population constituencies, our most extreme example here necessarily results in 400 Department A males, 1,600 Department B males, and 1,600 Department A females. This was a decision based on keeping the population N’s at 10,000 and certainly more extreme population constituency combinations could be examined in future like-minded explorations.

iterations), which yielded eight empirically-estimated standard errors of unweighted and weighted sample means. Figure 4 visually presents these standard errors in eight pairs of bars, demonstrating that the standard error of weighted sample means (red bar) tended to be 16% to 18% larger than that of unweighted sample means (grey bar) regardless of condition. These errors highlight the caveat that weighting should only be applied in the active nonresponse case (e.g., although the aggregate effect of weighting with passive nonresponse is error-minimizing, any one sampling condition is *more likely* to result in greater deviation from the population parameter when weighting is applied to sample data driven by passive nonresponse).

Collective roles of response rate, form, and attitudinal distribution

As an aggregate across sampling events, weighting always corrects sample bias, when it is present in the unweighted estimate. However, the standard errors suggest that for any *one* sampling event in the absence of bias, the likelihood that the sample mean approximates the *mean* of sample means is (slightly) greater for the unweighted estimate. When bias is present, however, (in the unweighted estimate) there is obviously no advantage to "being closer" to this biased mean of means. That is, under some circumstances, the mean of unweighted sample means does not center on the population mean. The implications of this seem quite obvious: Weighting should only be applied if bias is anticipated in the sample estimate. This may seem to be a picayune recommendation, but we note here that this advocation is not heeded in public opinion polling applications, where the computation and application of weights are default procedures (CITES? - perhaps AAPOR standards or personal communication with polling agencies such as Gallop).

Question for David - Can we look at the "crossing point?" (e.g., when MSE becomes excessive)

[perhaps David can derive/find a proof to parallel our results?] (Table 1

+ ResponseRate1 + SDForm2 + Figure 4) Maybe try to combine Figures 2 and 3 (put SD on Figure 3 - color code)

Added population attitudes (1/20/23) - not sure if this clutters but more consistent with flow of introduction

Discussion

We view nonresponse as a serious problem that should be addressed via repeated attempts to survey particularly reluctant or hard-to-reach respondents because nonresponse may be reasonably expected to be greatest in groups that are most unsatisfied [e.g., it may be typical for individuals representing these groups to have their responses diluted; see, for example, Taris and Schreurs (2007)]. However, several researchers have noted potentially misplaced relative emphasis on survey response rates, with Cook et al. (2000), Krosnick (1999), and Visser et al. (1996) articulating the point that representativeness of the sample is more important than response rate. We also believe that the goal in organizational surveying should be representativeness not exhaustiveness. Krosnick (1999) specifically comments that, even when probability sampling is employed, response rate does not necessarily implicate either good or poor sample representativeness. One aim of this paper is to reinforce this primary 'representativeness' orientation to those who may be otherwise inclined to focus on response rate as a sufficient index of quality (while also stressing sample weighting as a practice that can potentially remediate *mis*representativeness).

With the above in mind, we set out to answer three fairly straightforward questions: What roles do 1) response rate and 2) form of nonresponse have on population misrepresentation, and 3) what impact does the application of weights have on the quality of sample estimates? The simulations demonstrate that the impact of mere response rate impact *depends* on the underlying disttributions of population attitude. Conditions 1 through 3 (as well as all other conditions) are occasionally immune to response rate influence, depending on whether the pattern of nonresponse parallels the pattern of attitudinal distribution differences or not). Active forms of nonresponse can harm the unweighted sample estimate, but only when the pattern of active nonresponse is accompanied by differing distributions of attitudes within the active nonrespondent "populations" [this would appear to be a reasonable expectation based on the literature; e.g., Rogelberg et al. (2000); Rogelberg et al. (2003); Spitzmüller et al. (2007)]. Weighting "always" helps, as long as you capture the proper strata (which of course we were able to do via controlled simulation), but also… Although the weighted mean proved an unbiased estimate of the population mean across all simulations, in circumstances where no bias existed in the unweighted estimate, the trade-off between bias-correction and random error of precision (e.g., standard error) also needs to be acknowledged.

It may be noted here that the organizational surveying categorization of passive versus active somewhat parallels the broader statistical focus on data that is missing at random or completely at random (MAR or MCAR, see for example, Heitjan & Basu, 1996) versus data not missing at random (MNAR, see for example, Enders, 2011). Imputation is a common remediation technique for data MAR or MCAR whereas MNAR solutions may involve strategies such as latent variable estimation procedures (Muthén et al., 1987). In the context of organizational surveying, the current findings lead to a similar bifurcation of remediation methods - post-stratification weighting is recommended only in the circumstance of active nonresponse.

Previous presentations have noted that bias is sometimes associated with nonresponse and othertimes it is not - this research has not been explicit in the specific conditions that moderate this association, however. The current paper does make this association explicit. It is not merely the form of nonresponse that determines whether or not bias occurs, but also the underlying distributions that the response probabilities are applied to. Some distributional patterns are immune to the biasing effects of active nonresponse (see, for example, Conditions 1 through 3). Some patterns of active nonresponse also result in no bias even when distributional patterns deviate substantially (see, for example, Condition 8 where a 20%, 20%, 80%, 80% response rate pattern exhibits no error). The target therefore should not be merely form of nonresponse but also underlying attitudes. Regardless, however, weighting always remediates the error when it occurs (and does not add error where it is absent).

The current findings are of course qualified by the uniqueness of our simulations, most notably our ability to fully capture the correct population parameters (e.g., because these were "created" by us, we were also able to identify these strata as the nonresponse contributors). Even in the extreme conditions (e.g., a small "population" with a correspondingly low response rate; see, for example, the lower-left hand corner of Figure 2), the weighting algorithm was able to provide a bias correction. This is undoubtedly attributable to our random sampling procedure (instead of, for example, sampling conditionally from the population distributions), but here we do note that the raking procedure is applied at the "margins" (e.g., variable level, not interaction level), although our introduction of a biasing element is at the cell (interaction) level.

It has been stated that active nonresponse is relatively harmless unless the actively nonrespondent group is relatively large [cites below]. The current study, however, suggests that post-data-collection remediation. There may also be some important implications here regarding sample (and population) size. Because organizational surveyors likely interface with organizations of varying sizes (perhaps some of which are small- or medium-sized), the implications of our simulations particularly in the small population conditions, were highlighted. Findings specific to these conditions were: XXX, XXX, XXX.

There is of course no need to restrict weighting protocols to demographic groups - organizational surveyors have a rich tradition of attending to drivers of nonresponse (see, for example, Rogelberg & Stanton, 2007). Groupings of any sort can be the basis of weighting (for example, pre-survey probing might assign probabilities of nonresponse, and these probabilities can be retained post-administration as weighting guides.

It should also be pointed out that although the active nonrespondent group seems to be a great concern, it will not seriously bias the results unless the proportion of active nonrespondents is higher than 15% (Rogelberg et al., 2003; Rogelberg & Stanton, 2007; Werner et al., 2007). “In this study we found that the active nonrespondent group was relatively small (approximately 15%), but consistent in size with research conducted by .” (Rogelberg et al., 2003, pp. 1110–1111). “Furthermore, consistent with Roth (1994) who stated that when missingness is not random (as we found for active nonrespondents), meaningful bias will only be introduced if the group is relatively large (which was not the case in this study).” (Rogelberg et al., 2003, p. 1112).

“If the results show that the active nonrespondent group comprises a low proportion of the population, fewer concerns for bias arise. If the proportion of active respondents is greater than 15% of the group of individuals included in the interviews or focus groups (this has been the average rate in other studies), generalizability may be compromised.” (Rogelberg & Stanton, 2007, p. 201) * I believe there is an error here. The author want to say that if the proportion of active nonrespondents is greater than 15% of the group .

“It has been suggested that it takes a response rate of 85% to conclude that nonresponse error is not a threat (Dooely & Lindner, 2003). We agree that researchers should provide both empirical and theoretical evidence refuting nonresponse bias whenever the response rate is less than 85%.” (Werner et al., 2007, p. 293).

Note here however, the seeming disconnect between the reports of 15% active nonresponse and declining response rates (trending toward 50%). Certainly with decreasing overall response rates, the likely reasons would appear to be more active than passive (e.g., it is difficult to entertain the idea that potential respondents are more likely to forget to respond today than they were 40 years ago).

Integration of IT/IS systems within HR functions hopefully assists the (un)likelihood that organizatinoal population frames are either deficient or contaminated, although we note that this possibility (frame misspecification) is much more plausible within organziations that do not have updated or integrated HR IT/IS systems (perhaps, ironically, *smaller* organizations).

Limitations

The results are presented with at least three limitations: 1) our simulations are comprehensive, iterating through all possible combinations of response rates - those paralleling population distributions, those inversely mirroring population distributions, and those “orthogonal to” population distributions, 2) the “SD” operationalization of passive to active forms of nonresponse is a bit crude and insensitive to specific combinations of response rates expected to manifest or not manifest in bias, and 3) substantial bias may be present in the unweighted estimate even with only small proportions of active non-response (e.g., only one or two groups exhibiting slightly different response rates, with the resulting discrepancy [population versus sample mean] being quite large).

Future Directions

Our operationalization of passive nonresponse was based on realized subsample differences in response rate. Of course it is plausible that consistent response rates (e.g., 36%, 36%, 36%, 36%) could have corresponding *non-sampled* elements who represent active non-response. Our methodology did not model these scenarios, but future like-minded investigations may wish to do so.

A very practical implication of this study is that future organizational researchers may find more success implementing strategic sampling strategies as opposed to (or in addition to) pursuing response enhancement. That is, as a field, organizational researchers have been focused on response-enhancing strategies that minimize the presence of nonresponse. The current findings suggest that more careful adherence to random sampling from carefully constructed population frames may provide a different route to the same end-goal of sample representativeness.

Experimental methods within the psychological discipline have long been criticized for heavy reliance on samples of convenience (for instance, student samples). Very little progress has been made regarding the application of appropriate population sampling procedures in experimentation. Certain non-experimental procedures (most notably organizational surveying) hold paradoxical advantage over experimental procedures primarily in this arena of sampling - particularly in consideration of population coverage, which refers to the percent of a population that is reachable by the sampling procedure (e.g., postal, intra-office, or internet invitation) and likelihood of having access to population parameter estimates (e.g., strata constituencies). There is a rich tradition and literature of public opinion polling procedures and techniques from which to draw. These procedures, however, only hold advantage if the non-experimental methodologist acknowledges the criticality of sample representativeness. The current paper provides one corrective technique (post-stratification weighting) as an important focus for the organizational surveyor who shares this primary interest in maximizing sample representativeness.

We note the above "advantage" held by organizational surveyors because extensions of the current protocol include investigating how inaccurate census estimates (and/or grabbing the "wrong" group) affects the quality of sample estimates. That is, in our controlled simulations, we were able to know population constituencies, because they were set by us! In real-world applications, there is likely more error between the population estimate and actual population constituency. Similarly, if the association between attitude and group membership were to be controlled, there may be conditions identified whereby weighting loses its efficacy (e.g., low "correlations" between attitude and group membership). Future simulations should test boundary conditions for this type of error, identifying at what point inaccuracy in the population constituency estimate appreciably degrades the weighting procedure. Furthermore, it was demonstrated here that, when bias exists, weighting corrects it. Weighting also, however, results in a larger mean square error (MSE; expected spread of sample estimates around the population parameter). Feasibly then, there is a point at which the decreased bias is accompanied by an unacceptably inflated MSE. At which point does this occur? This is another fertile area for future exploration.

Most potential issues with weighting are addressed through careful consideration of the appropriate strata to take under consideration as well as ultimate level of aggregation (what group constitutes the population of interest or focus of feedback; e.g., regional, functional, or organizational?). We recommend the surveyor especially considers groups that might have issues of active forms of nonresponse and collect those demographics so weighting is an option. It is particularly in these contexts of 'unsatisfied' employees being less likely to respond to surveys that pre-stratification consideration becomes critical (for instance, if there is an inclination that attitudes may differ across, for example, night versus day shift workers, it is important that shift be measured and incorporated as a stratum prior to survey administration).

For Condition 5 (for example, low/high response rates with minority/majority population constituencies). The lower-right to upper-left diagonal reflects response rates that parallel population constituencies. The patterns across these stressors were consistent, with the weighted sample means (red dots) providing unbiased estimates of the population parameter, whereas the unweighted sample means (grey dots) tended to yield unbiased estimates when the population constituencies were roughly equal (e.g., close to 50%/50%).

Figure 3 drills down this information further by extracting unweighted and weighted estimates in one specific marginal population parameter combination (here, 60% males and 40% females; 40% in department A and 60% in department B). In doing so, the population parameters were in control and sample parameters were set free (see dotted red rectangle in Figure 2). Therefore, Figure 3 was then arranged in a fashion that allowed further investigation into the interactive effect of marginal sample parameters (gender on the x-axis and department on the y-axis) on the effectiveness of post-stratification weighting reflected by the pattern of grey and red dots. **Huh? - find old version or delete**

PRIOR TO RQs: after chatting with Yang (10/31/19) these need to be clarified a bit - reading 11/3 they make sense but need to be read very carefully. Check with Yang on 1/26 Skype. 2/1 revisions seem ok to Kulas. Three moving parts: underlying attitudinal distributions, response rate, and form of nonresponse <- perhaps we should make these variables more explicit prior to the procedure/results...
